

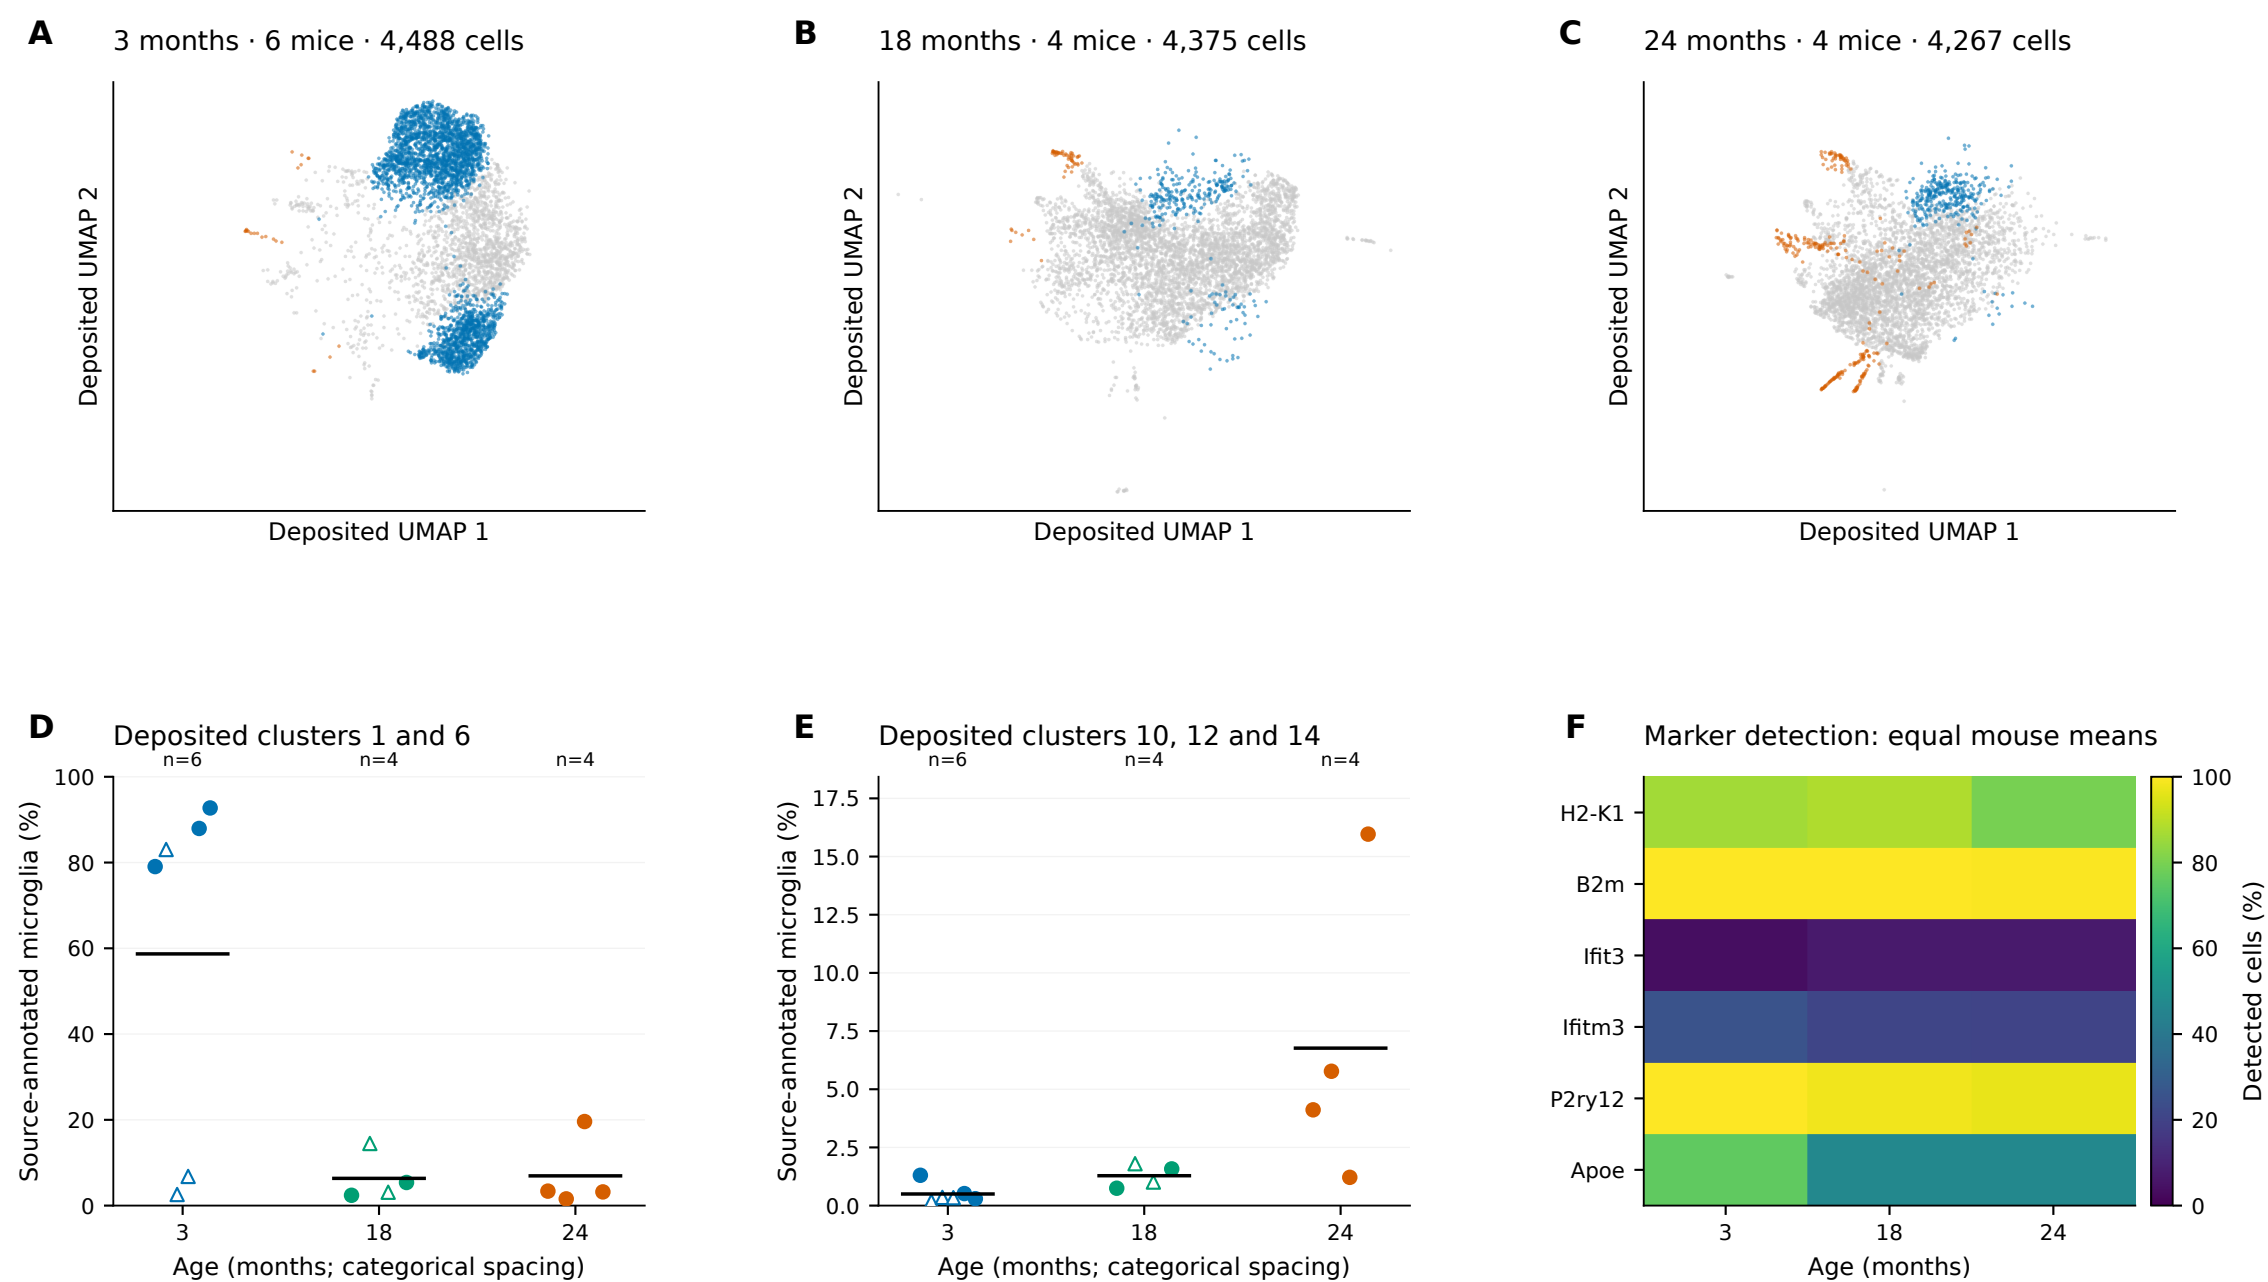

Figure 3 | Deposited microglial labels reveal age-associated occupancy, with source identity unresolved.

Rationale: An intermediate microglial state must be distinguished from changing proportions of existing states. The first step is to establish whether the deposited cells and cluster numbers correspond to those used in the published age comparison.

A–C, unchanged author UMAP coordinates for source-annotated microglia at 3, 18 and 24 months. Blue marks deposited Leiden labels 1/6, orange labels 10/12/14 and grey the remaining labels. D–E, individual-mouse occupancy and arithmetic means ($n = 6/4/4$); triangles are females and circles males. F, equal-mouse fractions with nonzero expression of fixed markers in deposited transformed X. The occupancy panels use different, explicitly labeled y-axis ranges.

Results: Labels 1/6 occupy 58.70%, 6.35% and 6.93% of microglia on average across the three ages; labels 10/12/14 occupy 0.50%, 1.28% and 6.77%. Cell counts and the inferred role of these numbered sets do not establish final-paper correspondence. No cluster was remapped to fit age, and no new trajectory was fitted. This is a deposit-concordance audit; it does not demonstrate a distinct intermediate state, a transition or Alzheimer-related function.
